LIST OF NOTATIONS

General

a	A scalar (integer or real)
\mathbb{R}	The set of real numbers
\mathbb{R}^d	The euclidean set of dimension d
$\ \cdot\ $	a norm of an euclidean set
$\text{dist}(\cdot, \cdot)$	A distance on a Polish space.
\mathbb{N}	The set of natural numbers
∇f	the gradient of a function $f : \mathbb{R}^d \rightarrow \mathbb{R}$

Statistical Learning Theory

\mathcal{Z}	Data space. In supervised learning, $\mathcal{Z} = (\mathcal{X}, \mathcal{Y})$ with \mathcal{X}, \mathcal{Y} input and label spaces
\mathbf{z}	A datum of \mathcal{Z} , in supervised learning $\mathbf{z} = (\mathbf{x}, y)$ with \mathbf{x} input and y label
\mathcal{S}	Learning sample $\mathcal{S} = \{\mathbf{z}_i\}_{i \geq 1}$
$\mathcal{D}_{\mathcal{S}}$	Distribution of \mathcal{S}
\mathcal{S}_m	Restriction of \mathcal{S} to its m first data $\mathcal{S}_m = \{\mathbf{z}_i\}_{i=1 \dots m}$
\mathcal{D}	For <i>i.i.d.</i> \mathcal{S} , distribution of a single datum on \mathcal{Z}
\mathcal{D}^m	For <i>i.i.d.</i> \mathcal{S} , distribution of \mathcal{S}_m
\mathcal{T}	For <i>i.i.d.</i> \mathcal{S} , Test set drawn from \mathcal{D}
\mathcal{H}	The set of hypotheses
h	A hypothesis $h \in \mathcal{H}$
ℓ	Loss function $\ell : \mathcal{H} \times \mathcal{Z} \rightarrow \mathbb{R}$

Probability Theory

$\mathbb{E}_{X \sim \nu} [\cdot]$	The expectation <i>w.r.t.</i> the random variable $X \sim \nu$
$\mathbb{P}_{X \sim \nu} [\cdot]$	The probability <i>w.r.t.</i> the random variable $X \sim \nu$
$\mathbb{1} [a]$	Indicator function; returns 1 if a is true and 0 otherwise
$(\mathcal{F}_i)_{i \geq 1}$	Filtration adapted to \mathcal{S}
$\mathbb{E}_i[\cdot]$	Conditional expectation <i>w.r.t.</i> \mathcal{F}_i , i.e. $\mathbb{E}_i[\cdot] := \mathbb{E}[\cdot \mid \mathcal{F}_i]$
$\mathcal{N}(\mu, \Sigma)$	Gaussian distribution on \mathbb{R}^d with mean μ and covariance matrix Σ

PAC-Bayes framework

$\mathcal{M}(\mathcal{H})$	Set of Probability densities <i>w.r.t.</i> the reference measure on \mathcal{H}
Q	Posterior distribution $Q \in \mathcal{M}(\mathcal{H})$ on \mathcal{H}
P	Prior distribution $P \in \mathcal{M}(\mathcal{H})$ on \mathcal{H}
$KL(Q \ P)$	Kullback-Leibler (KL) divergence between Q and P
$D_\alpha(Q \ P)$	Rényi Divergence between Q and P
$R_{\mathcal{D}}(h)$	Population Risk of $h \in \mathcal{H}$ <i>w.r.t.</i> \mathcal{D} , i.e. $R_{\mathcal{D}}(h) := \mathbb{E}_{\mathbf{z} \sim \mathcal{D}} [\ell(h, \mathbf{z})]$
$\hat{R}_{\mathcal{S}_m}(h)$	Empirical Risk on \mathcal{S}_m , i.e. $\hat{R}_{\mathcal{S}_m}(h) = \frac{1}{m} \sum_{i=1}^m \ell(h, \mathbf{z}_i)$
$\Delta_{\mathcal{S}_m}(h)$	Generalisation gap $\Delta_{\mathcal{S}_m}(h) := R_{\mathcal{D}}(h) - \hat{R}_{\mathcal{S}_m}(h)$
$R_{\mathcal{D}}(Q)$	Expected population risk <i>w.r.t.</i> Q , i.e. $R_{\mathcal{D}}(Q) := \mathbb{E}_{h \sim Q} [R_{\mathcal{D}}(h)]$
$\hat{R}_{\mathcal{S}_m}(Q)$	Expected empirical risk <i>w.r.t.</i> Q , $\hat{R}_{\mathcal{S}_m}(Q) := \mathbb{E}_{h \sim Q} [\hat{R}_{\mathcal{S}_m}(h)]$
$\Delta_{\mathcal{S}_m}(Q)$	Expected generalisation gap <i>w.r.t.</i> Q , $\Delta_{\mathcal{S}_m}(Q) := \mathbb{E}_{h \sim Q} [\Delta_{\mathcal{S}_m}(h)]$
$P_{-f(h)}$	Gibbs posterior associated to prior P and function $f : \mathcal{H} \rightarrow \mathbb{R}$

Optimal transport

W_1	The 1-Wasserstein distance
W_2	The 2-Wasserstein distance
$\Gamma(Q, P)$	Set of all coupling distribution on \mathcal{H}^2 whose marginals are Q and P .

PRÉAMBULE: APPRENTISSAGE HUMAIN, APPRENTISSAGE MACHINE ET GÉNÉRALISATION

Ce manuscrit étudie la question de la capacité de *généralisation* des algorithmes d'apprentissage machine. Pour comprendre la généralisation, il faut d'abord appréhender l'*apprentissage*, prenons donc le luxe, pour un bref instant, d'oublier les machines pour se concentrer sur l'apprentissage en ce qu'il a de plus humain.

Appréhender l'apprentissage humain. Un être apprenant, en premier lieu, va se structurer autour d'expériences, vécues ou transmises par autrui et va ensuite en bénéficier via diverses modalités. Il peut, par exemple, considérer une expérience médiée comme vraie (le feu brûle) et agir en fonction de ce postulat alors qu'à l'opposé, la répétition ou la négation de cette même expérience peuvent être symptomatiques d'une valeur de vérité nulle. Ces scénarios peuvent tout aussi bien apparaître pour une expérience vécue (hallucinations). Cette première dichotomie quant au traitement de l'information est intrinsèquement liée à une question clairement énoncée : est-ce que le feu brûle ? Puis-je me fier à mes sens ou ai-je halluciné ? Dans ces cas de figure, l'apprentissage a eu lieu à travers l'assujettissement de l'expérience à sa valeur de vérité par rapport à une question simple (ici à deux issues). Cette vision peut facilement s'étendre à une arborescence finie de possibles pour des questions à choix multiples. En effet, on peut étendre la question de la brûlure comme suit : quelle est l'intensité de la brûlure en fonction de la température du feu ? On peut dès lors établir une multitude de réponses représentant divers degrés de brûlure.

Néanmoins, de nombreuses questions ne peuvent se réduire à un nombre fini de possibilités. Par exemple, qu'est-ce que le feu ? Pour répondre à cette question, il est néanmoins possible d'exploiter de multiples facettes d'expériences (feu de bois, brindille, roche) pour proposer le feu comme étant la réaction chimique de l'oxygène de l'air avec un matériau combustible, un apport d'énergie servant de déclencheur.

Il est alors légitime de se demander pourquoi l'apprenant a eu besoin de comprendre la vraie nature du feu. Cette compréhension fondamentale des choses émerge de considérations pratiques : comment ne plus avoir froid ? Peut-on manger de la viande autrement que crue pour diminuer les risques de maladie ? Il faut alors de multiples interactions avec l'environnement pour générer des expériences et ensuite apprendre d'elles pour répondre graduellement à un besoin complexe (comment faire un feu pour se réchauffer?).

Ainsi, par cette analyse préliminaire, nous avons trouvé plusieurs prémices de compréhension de l'apprentissage chez l'homme.

- Comment l'apprentissage se formalise-t-il structurellement ? L'apprenant doit abâtardir l'expérience à des questions simples pour acquérir des certitudes primaires. Ces dernières acquises, il est possible d'atteindre des questions complexes en imbriquant de plus en plus de considérations élémentaires.
- D'où provient le besoin d'apprendre ? D'un point de vue pratique, l'émergence de ces questions complexes dérive bien souvent d'un rapport de l'être à son environnement, permettant d'élaborer des objectifs contextuels. L'apprenant devient alors graduellement capable de répondre à des besoins complexes par une succession d'actions simples.

De l'apprentissage humain à l'apprentissage machine. L'apprentissage machine s'est structuré autour de deux approches, une première symbolique qui tire profit des extrapolations humaines pour apprendre à la machine à manipuler une axiomatique et une seconde, statistique, qui consiste à fournir bon nombre d'expériences à la machine pour lui faire apprendre par de multiples exemples empiriques. Nous allons nous focaliser sur la seconde approche car, elle sous-tend une large partie de la recherche moderne. Cette méthode requiert de nombreuses expériences transmises à la machine qui en extrait les connaissances à travers des procédures optimisatoires. Plus précisément, la connaissance extraite dépend de la question posée ainsi que sa traduction mathématique. Nous pouvons alors relever des parallèles avec l'apprentissage humain décrit plus haut: il faut des expériences et une question pour réduire le réel à quelque chose d'apprenable. Pour aller plus loin, la variété des scénarii d'apprentissages humains décrits au dessus ont une correspondance dans l'apprentissage machine moderne: à la question "Le feu brûle-t-il?" on peut associer l'apprentissage supervisé qui traite d'apprendre sur des questions à choix multiples. A la question "qu'est-ce que le feu?", on peut associer l'apprentissage non-supervisé qui va chercher, dans le cas du clustering (ou regroupement), des similitudes non-induites par la question entre diverses expériences. Finalement, quant à l'interaction avec l'environnement et la question "puis-je faire un feu?", elle est associée à l'apprentissage par renforcement qui étudie l'apprentissage d'un agent qui interagit avec son environnement.

Comprendre la généralisation depuis l'apprentissage. La généralisation peut être vue comme la capacité d'exploiter l'apprentissage d'une expérience au delà de cette dernière. Cela englobe une compréhension théorique et axiomatique d'un phénomène bien au delà de l'expérience en elle-même, *i.e.* une extrapolation fructueuse ou bien la capacité à exploiter la connaissance acquise pour une situation inédite, présentant des similitudes avec divers vécus, *i.e.* interpoler des expériences.

Ce double aspect de la généralisation se retrouve aussi bien chez l'homme que la machine sous diverses modalités. Les réseaux de neurones profonds, qui sont le fer de lance de l'apprentissage machine moderne, se basent sur des espaces de dimension finie pour apprendre, ce qui revient à dire qu'un problème peut être appris à travers un nombre fini de principes fondateurs. Le nombre de principes pouvant être augmentés autant que les capacités numériques le permettent, nous dirons alors que les réseaux de neurones ont une puissance discrète de généralisation. Etant donné que les méthodes d'apprentissage machine sont corrélées à leur pendantes humaines, on peut alors se demander si la puissance de généralisation (et même d'apprentissage) humaine est également discrète. Cette affirmation semble cavalière, car même s'il est possible de supposer que la part consciente de l'esprit humain raisonne à horizon finie et a une puissance dénombrable (transmise d'ailleurs à la machine, apprenant selon des modalités humaines), cette dimension occulte la quantité d'information sans cesse captée et filtrée par notre cerveau ainsi que son assimilation inconsciente, relevant autant de la pensée abstraite que du biologique peut potentiellement générer une puissance de généralisation relevant d'un infini plus large et ainsi fournir une puissance de généralisation continue (relevant davantage de la ligne que du point). Dès lors, comment penser la généralisation chez l'homme alors que, mathématiquement, nos intuitions les plus simples nous font défaut lorsque cette puissance continue intervient (la boule de rayon 1 n'est pas compacte en dimension infinie, RIESZ, 1955)? On peut également se demander si l'extrapolation existe dans de telles structures ou si tout revient à interpoler (HASSON *et al.*, 2020).

Quid de la généralisation en apprentissage machine de nos jours? Qu'espérer alors des réseaux de neurones artificiels et de leur capacité de généralisation relativement à l'humain? Les théorèmes d'approximations universels (voir e.g. LU *et al.*, 2017; PARK *et al.*, 2021) assurent que les réseaux de neurones sont capables d'approximer n'importe quelle fonction vivant dans un espace à la puissance du continu (e.g. l'espace de Banach des fonctions continues à support compact qui n'admet pas de base dénombrable), faisant de ces structures des candidats prometteurs pour appréhender les mécanismes humains de généralisation. Les approximations prodiguées par ces machines seront, dans un avenir proche, potentiellement suffisamment puissantes pour donner l'illusion d'une capacité de généralisation humaine. Néanmoins, il demeure bon de garder en tête que, si la thèse d'une inégalité fondamentale de nature entre les puissances de généralisation humaine et machine est avérée, alors les réseaux de neurones artificiels n'atteindront jamais pleinement les capacités de compréhension du monde de leurs homologues biologiques. Reste que la qualité de leurs approximations font de ces structures des assistants de valeur, enrichissant les capacités de chacun. Mieux comprendre la puissance de généralisation machine, être capable de la quantifier, d'identifier les mécanismes qui la favorisent sont les objets de ce manuscrit.

PREAMBLE: HUMAN LEARNING, MACHINE LEARNING AND GENERALISATION

This manuscript tackles the notion of *generalisation* a notion built upon the general notion of *learning*. For a brief moment, let's take the luxury of forgetting about machines and concentrate on learning at its most human.

Apprehending human learning A human being (here a learner) is structured around experiences, either lived or passed on by others.

The learner then benefits from these experiences in various ways, for instance, by considering a mediated experience to be true (fire burns) and acting according to this. On the contrary, reiteration or denial of this same information may be symptoms of zero truth value. These scenarios can just as easily appear for a lived experience (the question of hallucinations). This first dichotomy in information processing is intrinsically linked to a clearly stated question: does fire burn? Can I trust my senses or have I hallucinated? In these cases, learning has taken place by reducing the intrinsic complexity of an experience to its truth value *w.r.t.* a simple question (in this case with two outcomes). This vision can easily be extended to a finite tree of possibilities through multiple-choice questions. Indeed, we can extend the burning question as follows: what is the intensity of the burn as a function of the temperature of the fire? We can then establish a multitude of answers representing various degrees of burn.

However, many questions cannot be reduced to a finite number of possibilities. For example, what is fire? To answer this question, it is nevertheless possible to exploit multiple facets of experience (wood, twig, rock fire) to propose that fire is the chemical reaction of oxygen in the air with a combustible material, with a supply of energy serving as the trigger.

Then, a legitimate question is: why has mankind understood the nature of fire? This fundamental understanding emerged from practical considerations: how can we stop being cold? Can we eat meat other than raw to reduce the risk of illness? It then takes multiple interactions with the environment to generate experiences and then learn from them to gradually respond to a complex need (how to make a fire to keep yourself warm?).

Thus, through this preliminary analysis, we have found several premises of understanding human learning.

- How is learning formalised structurally? The learner must base the experience on simple questions to acquire primary certainties. These latter acquired, it is possible to reach complex questions by interweaving more and more elementary considerations.
- Where does the need to learn come from? From a practical point of view, the emergence of these complex questions often arises from a relationship between the being and its environment, making it possible to develop contextual objectives. The learner then gradually becomes capable of responding to complex needs through a succession of simple actions.

From human to machine learning Machine learning has been structured around two approaches, the first is symbolic and takes advantage of human extrapolations to teach the machine to manipulate an axiomatic, while the second is statistical, and consists of providing the machine with a large number of experiments so that it learns from multiple empirical examples. We are going to focus on the second approach because it underpins a large part of modern research. This method requires a large number of experiments to be transmitted to the machine, which then extracts the knowledge through optimising procedures. More precisely, the knowledge extracted depends on the question posed and its mathematical translation. We can see parallels with human learning described above: you need experiments and a question to reduce reality to something learnable. To go a step further, the variety of human learning scenarios described above can be applied to modern machine learning: the question "Does fire burn?" can be associated with supervised learning, which learns from multiple-choice questions. The question "What is fire?" can be associated with unsupervised learning, which, in the case of clustering, looks for similarities between numerous experiments that are not induced by the question. Finally, the question "Can I make a fire?" can be linked to reinforcement learning which focuses on the evolution of an agent learning from its interaction with the environment.

From learning to generalisation. Generalisation can be seen as the ability to exploit learning from experience beyond that experience. This encompasses a theoretical and axiomatic understanding of a phenomenon, *i.e.* a fruitful extrapolation, or the ability to exploit the knowledge acquired for a new, yet showing similarities, situations *i.e.* to interpolate experiences.

This dual aspect of generalisation can be found in both humans and machines in a variety of ways. Deep neural networks, which are the spearhead of modern machine learning, are based on finite-dimensional learning spaces, which means that a problem can be learned through a finite number of founding principles. Since the number of principles can be increased as far as numerical capacity allows, we can say that neural networks have discrete generalising power. Given that machine learning methods are

correlated with their human counterparts, we might then ask whether the power of human generalisation (and even learning) is also discrete. This assertion is somewhat bold as even it is assumable that the conscious part of the human mind reasons on a finite horizon and has a discrete generalisation power (transmitted, moreover, to the machine, which learns according to human methods), this dimension obscures the quantity of information constantly captured and filtered by our brain, as well as its unconscious assimilation. In other words, the fact that our brain is as much a part of abstract thought as it is of biological thought can potentially generate a generalisation power that relates to a wider infinity and thus provide a continuous generalisation power (relating more to the line than to the point). So how can we think about generalisation in humans when, mathematically, our simplest intuitions fail us when this continuous power is involved (the ball of radius 1 is not compact in infinite dimension, RIESZ, 1955)? We might also ask whether extrapolation exists in such structures or whether it all boils down to interpolation (HASSON *et al.*, 2020).

What to expect from generalisation in modern machine learning? So what can we expect from artificial neural networks and their ability to generalise to humans? Universal approximation theorems (see *e.g.* LU *et al.*, 2017; PARK *et al.*, 2021) ensure that neural networks are capable of approximating any function living in a space to the power of the continuum (*e.g.* the space of continuous functions with compact support which does not admit a countable base as a Banach space), making these structures promising candidates for partially understanding human generalisation mechanisms. In the near future, machine approximations will potentially be powerful enough to give the illusion of human generalisation capacity. Nevertheless, it is worth bearing in mind that, if the thesis of a fundamental inequality in nature between the powers of human and machine generalisation is confirmed, then artificial neural networks will never fully attain the world-understanding capacities of their human counterparts. It is still worth noticing artificial neural nets ability to approximate this human intelligence makes these structures valuable assistants, enriching the capabilities of any individual. That being said, this manuscript aims to provide a better understanding of generalisation in machine learning, quantifying and indentifying the mechanisms that promote it.

CHALLENGE HERE: being very rigorous on the lit review.

PAC-BAYES LEARNING, A FIELD OF MANY PARADIGMS

1.1 A brief introduction to statistical learning

Statistical learning (VAPNIK, 1999; JAMES *et al.*, 2013) quantifies and identifies how learning algorithms, trained on a specific task using a finite training dataset, generalise to novel, unseen datum. More precisely, an agent has to learn how to answer a question, formalised as a *learning problem* being a tuple $(\mathcal{H}, \mathcal{Z}, \ell)$ composed of a *predictor space* on which evolves the agent during the learning process, a *data space* \mathcal{Z} and a *loss function* being the mathematical formulation of the question. Such a minimalistic structure is convenient to encompass a broad range of real-life learning scenarii. To learn, the agent has access to a *training dataset* $\mathcal{S}_m = (\mathbf{z}_i)_{i=1\dots m}$. The most classical way to learn from \mathcal{S}_m is the empirical risk minimisation (ERM), minimising the *empirical risk* $\hat{R}_{\mathcal{S}_m} := \frac{1}{m} \sum_{i=1}^m \ell(h, \mathbf{z}_i)$. In this setting, when \mathcal{S}_m is *i.i.d.* (following the distribution \mathcal{D}), two facets of generalisation are commonly studied in statistical learning for an agent $h \in \mathcal{H}$.

- First, the *population risk* $R_{\mathcal{D}}(h) := \mathbb{E}_{\mathbf{z} \sim \mathcal{D}}[\ell(h, \mathbf{z})]$ focus on the average performance of our learning agent *w.r.t.* any new situation $\mathbf{z} \in \mathcal{D}$, independent of \mathcal{S}_m , possibly faced by the agent. A small population risk ensure then efficient generalisation.
- Second, the *generalisation gap* $\Delta_{\mathcal{S}_m}(h) := R_{\mathcal{D}}(h) - \hat{R}_{\mathcal{S}_m}(h)$ evaluate the coherence between the empirical risk and the population one. Having a small generalisation gap ensure that the generalisation ability of the agent has the same magnitude than its training performance.

Note that the population risk is a stronger notion of generalisation than the generalisation gap. However, a small generalisation gap (in absolute value) as well as a small empirical risk is enough to ensure a good population risk. Given that modern optimisation algorithm often yield small empirical risk, the generalisation gap has received a particular attention in statistical learning.

Generalisation bounds. Generalisation bounds are inequalities controlling the generalisation gap (or the population risk) by various quantities depending either on \mathcal{H} , \mathcal{Z} or \mathcal{S}_m . We propose below general patterns usually involved in generalisation bounds for an agent $h_{\mathcal{S}_m} \in \mathcal{H}$ depending on \mathcal{S}_m (for instance the output of the ERM).

Expected generalisation bound. For any training set \mathcal{S}_m :

$$\mathbb{E}_{\mathcal{S}_m} [\Delta_{\mathcal{S}_m}(h_{\mathcal{S}_m})] \leq f\left(\text{COMPLEXITY}, \frac{1}{m}\right). \quad (1.1)$$

High-probability generalisation bounds. For any training set \mathcal{S}_m , with probability $1 - \delta$ over the draw of \mathcal{S}_m :

$$\Delta_{\mathcal{S}_m}(h_{\mathcal{S}_m}) \leq f\left(\text{COMPLEXITY}, \frac{1}{m}, \log \frac{1}{\delta}\right). \quad (1.2)$$

The nature of f and the COMPLEXITY term depend on the facet of the complexity of the learning problem we aim to focus. Celebrated examples are for instance the dimension of \mathcal{H} , if euclidean, the VC dimension of \mathcal{H} (VAPNIK, 2000), the Rademacher complexity (BARTLETT and MENDELSON, 2001, 2002), the stability parameter of a learning algorithm (BOUSQUET and ELISSEEFF, 2000) or the subgaussian diameter of \mathcal{Z} (KONTOROVICH, 2014). Another approach relies on the Bayesian learning paradigm, deriving *posterior* knowledge from data and prior modelling of the environment. Then, the COMPLEXITY can be borrowed from information theory (COVER and THOMAS, 2001), e.g. mutual information (NEAL, 2012), or from optimal transport, e.g. Wasserstein distances (WANG *et al.*, 2019; RODRIGUEZ-GALVEZ *et al.*, 2021).

Those two approaches have various benefits. A notable strength of expected bounds is that they may reach fast convergence rates (*i.e.* faster than $\frac{1}{\sqrt{m}}$) contrary to high-probability one, even when \mathcal{H} is a singleton thanks to the central limit theorem (GRUNWALD *et al.*, 2021). However, expected bounds often involves a theoretical COMPLEXITY which cannot be estimated in practice and may be hard to interpret while high probability bounds may be fully empirical and can be considered with small confidence parameter δ as it is attenuated by a logarithm.

How to choose the complexity term ? An introductory example. There is no evidence proving that a certain notion of complexity is preferable to another. The choice of COMPLEXITY may however be driven by practical considerations, emerging from the learning problem of interest. To illustrate this point, let us focus on the following example, providing two learning problems which differs only from the predictor space \mathcal{H} and which have very different interactions with the VC dimension.

Example 1.1.1. Consider a supervised learning problem where $\mathcal{Z} = \mathbb{R}^k \times \mathcal{Y}$ with $\mathcal{Y} = \{0, 1\}$, k smaller than m and with loss $\ell(h, (x, y)) = \mathbb{1}\{h(x) \neq y\}$. First, assume that \mathcal{H} is the set of linear classifiers; *i.e.* $\mathcal{H}_1 := \{h_\theta(x) = \text{sgn}(\langle \theta, x \rangle)\}$, where $\text{sgn}(a)$ denotes the sign of a . In this case, using the VC dimension may lead to non-vacuous generalisation bounds (VAPNIK, 2000).

1.2. An information-theoretic exposition of PAC-Bayes learning

However, in modern machine learning, deep neural networks are often considered, let us first define a celebrated class of deep neural networks.

Definition 1.1.1. A multilayer perceptron with depth K and architecture $\{N_1, \dots, N_K\}$, denoted as $h_{\mathbf{w}}(\mathbf{x}) := Wh^K(\dots h^1(\mathbf{x})) + b$, is composed of K layers $h^1(\cdot), \dots, h^K(\cdot)$. $W \in \mathbb{R}^{|\mathcal{Y}| \times N_K}$ and $b \in \mathbb{R}^{N_K}$ are the weight matrix and the bias of the last layer, and the i -th layer h^i , composed of N_i nodes, is defined by $h^i(\mathbf{x}) := \sigma_i(W_i \mathbf{x} + b_i)$, where $W_i \in \mathbb{R}^{N_i \times N_{i-1}}$ and the bias $b_i \in \mathbb{R}^{N_i}$ are its weight matrix and bias respectively; $\sigma_i : \mathbb{R}^{N_i} \rightarrow \mathbb{R}^{N_i}$ is an activation function. The weights $\mathbf{w} = \text{vec}(\{W, W_K, \dots, W_1, b, b_K, \dots, b_1\})$ represent the vectorisation of all parameters of the network.

Now, consider the learning problem with the same \mathcal{Z}, ℓ as above, but with \mathcal{H}_2 being the set of multilayer perceptrons *w.r.t.* a fixed depth K and architecture $\{N_1, \dots, N_K\}$. To be consistent with modern practice, assume also that we are in the *overparametrised setting*, meaning that the space \mathcal{H}_2 has a dimension d far greater than m . In this case, VC dimension fails to explain the good generalisation ability (seen in practice) of multilayer perceptrons (BARTLETT and MAASS, 2003).

Understanding the generalisation ability of deep neural networks remains nowadays a major challenge and in what follows, we focus on a modern branch of learning theory which provided non-vacuous bounds of the generalisation ability of deep neural networks: PAC-Bayes learning.

1.2 An information-theoretic exposition of PAC-Bayes learning

PAC-Bayes learning is a recent branch of learning theory which emerged in the late 90s via the seminal work of (SHAWE-TAYLOR and WILLIAMSON, 1997; MCALLESTER, 1998, 1999, 2003) and later pursued by (CATONI, 2003, 2007). Modern surveys are available to describe the various advances in the field (GUEDJ, 2019; HELLSTRÖM *et al.*, 2023; ALQUIER, 2024). Similarly to the various subfields of statistical learning described in Section 1.1, PAC-Bayes theory provide generalisation bounds involving a COMPLEXITY term apprehending a facet of the complexity of the learning problem. In PAC-Bayes, this term is inspired from the Bayesian learning paradigm of designing a *posterior* knowledge of the learning problem based on both training data and a *prior* knowledge of the considered situation. A concrete example of Bayesian learning would be an explorer mapping an ill-known territory. The explorer has to adapt the existing maps at its disposal before exploration to its discoveries. Doing so, he creates an

a *posteriori* map imbricating the benefits of both the prior knowledge alongside its findings. From a mathematical perspective, the Bayes approach relies on the Bayes formula, providing an update recipe from a prior distribution $P \in \mathcal{M}(\mathcal{H})$ over the predictor space \mathcal{H} to a posterior $Q \in \mathcal{M}(\mathcal{H})$ through a likelihood. On the contrary, PAC-Bayes, while inspired from the Bayesian philosophy, does not relies on the Bayes formula but instead on tools from information theory. This general approach benefits from additional flexibility as PAC-Bayes can be linked and applied to Bayesian learning (see GUEDJ, 2019) but also blurs the notion of prior and posterior distributions, now independent of the fundamental Bayes formula. We further develop those points through two celebrated high-probability bounds: the McAllester and Catoni ones.

Two fundamental results

The McAllester's bound (MCALLESTER, 2003) enriched with Maurer's trick (MAURER, 2004) and Catoni's bound (ALQUIER *et al.*, 2016, Theorem 4.1, being a relaxation of CATONI, 2007, Theorem 1.2.6) are probably the most known high-probability PAC-Bayes bounds. We recall them in Proposition 1.2.1.

Proposition 1.2.1. Assume \mathcal{S}_m to be *i.i.d.*

McAllester's bound, (Maurer, 2004, Theorem 5). For any $\delta \in (0, 1)$, $\ell \in [0, 1]$, any data-free prior $P \in \mathcal{M}(\mathcal{H})$, with probability at least $1 - \delta$, for any posterior $Q \in \mathcal{M}(\mathcal{H})$,

$$\Delta_{\mathcal{S}_m}(Q) \leq \sqrt{\frac{\text{KL}(Q, P) + \ln \frac{2\sqrt{m}}{\delta}}{2m}}. \quad (1.3)$$

Catoni's bound, (Alquier *et al.*, 2016, Theorem 4.1). For any $\lambda \in \mathbb{R}/\{0\}$, $\delta \in (0, 1)$, ℓ being σ^2 -subgaussian and a data-free prior P , with probability at least $1 - \delta$ over \mathcal{S} , for any $Q \in \mathcal{M}(\mathcal{H})$,

$$\Delta_{\mathcal{S}_m}(Q) \leq \frac{\text{KL}(Q, P) + \log(1/\delta)}{\lambda} + \frac{\lambda \sigma^2}{2m}. \quad (1.4)$$

For both results, $\Delta_{\mathcal{S}_m}(Q)$ denotes the expected generalisation gap *w.r.t.* Q and KL denotes the Kullback-Leibler divergence.

Recall that a random variable X is σ^2 -subgaussian if for any $\lambda \in \mathbb{R}$, $\mathbb{E}[\exp(\lambda(X - \mathbb{E}[X]))] \leq \exp\left(\frac{\lambda^2 \sigma^2}{2}\right)$ and that any loss $\ell \in [0, C]$ is C -subgaussian. Both McAllester and Catoni bounds fit the general shape of (1.2). In both cases, $\text{COMPLEXITY} = \text{KL}(Q, P)$ and f varies. The immediate link with the Bayesian philosophy of learning

1.2. An information-theoretic exposition of PAC-Bayes learning

is that the prior has to be data-free. However, (1.3) and (1.4) are both valid simultaneously for any posterior, which is strictly more general than considering the Bayesian posterior. Note that if λ is optimised, then Catoni's bound would boil down to an upgraded McAllester bound without the $\log(\sqrt{m})$ term, but such an optimisation is not feasible as λ has to be chosen independently of the dataset \mathcal{S}_m . Note that this gap has been recently filled by DUPUIS and ŞİMŞEKLI (2024, Theorem 33). While the theoretical links between those two bounds are clear, they involve two different toolboxes: McAllester's bound heavily relies on the KL divergence between Bernoullis alongside calculation tricks exploiting the boundedness of the loss while the original Catoni's bound (CATONI, 2007, Theorem 1.2.6) exploits tools from statistical physics. The relaxation (1.4) proposed here is reachable by a few key arguments, involved in a vast majority of PAC-Bayes proofs. We propose it below for pedagogical purpose.

Proof of Equation (1.4). Note that the first part of the proof holds for a large part of PAC-Bayes literature. **A generic pattern for PAC-Bayes bounds.** This part is designed upon two cornerstones, retrievable in many existing results: the change of measure inequality (CSISZÁR, 1975; DONSKER and VARADHAN, 1976 – see also BANERJEE, 2006; GUEDJ, 2019 for a proof) and Markov's inequality.

Lemma 1.2.1 (Change of measure inequality). For any measurable function $\psi : \mathcal{H} \rightarrow \mathbb{R}$ and any distributions Q, P on \mathcal{H} :

$$\mathbb{E}_{h \sim Q}[\psi(h)] \leq \text{KL}(Q, P) + \log(\mathbb{E}_{h \sim P}[\exp(\psi(h))]).$$

For a given $\lambda > 0$, the change of measure inequality is then applied to a certain function $f_m : \mathcal{H} \rightarrow \mathbb{R}$, possibly involving \mathcal{S}_m : for all posteriors Q ,

$$\mathbb{E}_{h \sim Q}[f_m(h)] \leq \text{KL}(Q, P) + \log(\mathbb{E}_{h \sim P}[\exp(f_m(h))]). \quad (1.5)$$

To deal with the random variable $X(\mathcal{S}_m) := \mathbb{E}_{h \sim P}[\exp(f_m(h))]$, our second building block is Markov's inequality ($\mathbb{P}(X > a) \leq \frac{\mathbb{E}[X]}{a}$) which we apply for a fixed $\delta \in (0, 1)$ on $X(\mathcal{S}_m)$ with $a = \mathbb{E}_{\mathcal{S}_m}[X(\mathcal{S}_m)]/\delta$. Taking the complementary event gives that for any m , with probability at least $1 - \delta$ over the sample \mathcal{S}_m , $X(\mathcal{S}_m) \leq \mathbb{E}_{\mathcal{S}_m}[X(\mathcal{S}_m)]/\delta$, thus:

$$\mathbb{E}_{h \sim Q}[f_m(h)] \leq \text{KL}(Q, P) + \log(1/\delta) + \log(\mathbb{E}_{h \sim P} \mathbb{E}_{\mathcal{S}_m}[\exp(f_m(h))]). \quad (1.6)$$

Note that in (1.6), we swapped the two expectations in the last term thanks to Fubini's theorem and the fact that P is data-free.

Proving Catoni's bound. Now, we take $f_m(h) = \lambda \Delta_{\mathcal{S}_m}$ and consider for any $h \in \mathcal{H}$, $A(h) = \mathbb{E}_{\mathcal{S}_m}[\exp(f_m(h))]$.

Note that, given \mathcal{S}_m is iid,

$$A(h) = \prod_{i=1}^m \mathbb{E}_{\mathcal{S}_m} \left[\exp \left(\frac{\lambda}{m} (\mathcal{R}_{\mathcal{D}}(h) - \ell(h, \mathbf{z}_i)) \right) \right],$$

and thanks to Hoeffding's lemma alongside ℓ being σ^2 -subgaussian,

$$A(h) \leq \prod_{i=1}^m \exp \left(\frac{\lambda^2 \sigma^2}{2m^2} \right) = \exp \left(\frac{\lambda^2 \sigma^2}{2m} \right).$$

Plugging this upper bound in (1.6) and dividing by λ concludes the proof. ■

The generic pattern (1.6), allows to retrieve many PAC-Bayes bounds, starting with McAllester's one, where $f_m = kl(\mathcal{R}_{\mathcal{D}}(h), \hat{\mathcal{R}}_{\mathcal{S}_m}(h))$, kl being the KL divergence between Bernoullis and completing with the subtle calculations of MAURER (2004). This pattern is also valid, for instance, for the results of GERMAIN *et al.* (2009), the Bernstein PAC-Bayesian bounds of TOLSTIKHIN and SELDIN (2013) and MHAMMEDI *et al.* (2019) and many other results, *e.g.* THIEMANN *et al.* (2017), GUEDJ and ROBBIANO (2018), HOLLAND (2019), and WU and SELDIN (2022). This then pins two major points for a large part of PAC-Bayes literature:

1. Interpreting PAC-Bayes from a Bayesian point of view is legitimated by the change of measure inequality, yet the KL divergence. More generally, this property allows interpreting PAC-Bayes under a more general information-theoretic paradigm, where relevant prior information is transferred to the posterior (here by absolute continuity to keep the KL finite). This information-theoretic vision is also retrieved in in-expectation PAC-Bayes bounds, where mutual information can be considered instead of KL divergence (RUSSO and ZOU, 2016; XU and RAGINSKY, 2017; HELLSTRÖM and DURISI, 2020; STEINKE and ZAKYNTHINO, 2020; GRUNWALD *et al.*, 2021; HELLSTRÖM and DURISI, 2022).
2. The statistical properties of the learning problem are linked to the exponential moment coming from the change of measure inequality, this often implies the strong assumptions of Proposition 1.2.1: data-free prior, bounded or subgaussian losses (sometimes attenuated to subexponentiality CATONI, 2004).

A theory suited for Example 1.1.1? The two previous points show that Proposition 1.2.1 holds for learning problem with light-tailed losses (often bounded), *i.i.d.* data, encompassing classification tasks for instance. Then, PAC-Bayes learning seems

1.3. From theory to learning algorithms

suited to understand, on such problems, the McAllester and Catoni bounds are suited to the learning problem $(\mathcal{H}_2, \mathcal{Z}, \ell)$ of Example 1.1.1.

However, the question of their tightness is unsolved as we do not know the behavior of the KL term in practice. Furthermore the question of which distribution Q should be taken in Proposition 1.2.1 remains open. Hopefully, PAC-Bayes bounds can be transformed into learning algorithms.

1.3 From theory to learning algorithms

Algorithms associated to McAllester and Catoni bounds

A shared particularity of McAllester and Catoni bounds is that they are both fully empirical. Then it is possible to minimise them in practice and thus, deriving new theory-driven learning algorithms which are expected to have at worse, a small generalisation gap and at best, a small population risk. More precisely, learning algorithms associated to Proposition 1.2.1 are stated below:

$$Q_M := \operatorname{argmin}_{Q \in \mathcal{C}} \hat{R}_{S_m}(Q) + \sqrt{\frac{\text{KL}(Q, P)}{2m}}. \quad (1.7)$$

For any $\lambda > 0$,

$$Q_C := \operatorname{argmin}_{Q \in \mathcal{C}} \hat{R}_{S_m}(Q) + \frac{\text{KL}(Q, P)}{\lambda}. \quad (1.8)$$

In both cases, $\mathcal{C} \subseteq \mathcal{M}(\mathcal{H})$ is the class of distributions on which we optimise. The choice of \mathcal{C} can come from a priori knowledge of the problem or from optimisation concerns to make the KL divergence tractable.

Knowing Catoni's bound is a relaxation of McAllester's one, it seems more natural to consider Q_M over Q_C . However, the presence of a square root in (1.7) can be challenging for practical optimisation. We illustrate this below.

Example 1.3.1. Consider the case where, for a given $\sigma > 0$, $\mathcal{C} = \{\mathcal{N}(\mu, \sigma^2 \text{Id}) \mid \mu \in \mathbb{R}^d\}$. Then for any $P = \mathcal{N}(\mu_1, \sigma^2 \text{Id})$, $Q = \mathcal{N}(\mu_2, \sigma^2 \text{Id})$, $\text{KL}(Q, P) = \frac{\|\mu_1 - \mu_2\|^2}{2\sigma^2}$. Then, optimising (1.7) in this case implies to lose the strong convexity of the KL divergence while it is retained for (1.8).

Another practical advantage of (1.8) over (1.7) emerges when $\mathcal{C} = \mathcal{M}(\mathcal{H})$. In this case, Catoni's bound admits a closed form solution, while McAllester's one should be numerically optimised on all the space of distributions, which is not feasible. This closed form, extracted from CATONI (2003, Section 5.1), is recalled below.

$$\text{When } \mathcal{C} = \mathcal{M}(\mathcal{H}), \quad dQ_C(h) = \frac{\exp(-\lambda \hat{R}_{S_m}(h))}{\mathbb{E}_{h \sim P}[\exp(-\lambda \hat{R}_{S_m}(h))]} dP(h) \quad (1.9)$$

Then, $Q_C = P_{-\lambda \hat{R}_{S_m}}$ is the *Gibbs posterior* associated to $P, \lambda \hat{R}_{S_m}$. By introducing Gibbs posterior in statistical learning, CATONI (2007) draws a theoretical link between statistical physics and learning theory. Unfortunately, Gibbs posteriors often require Monte Carlo methods to be implemented, which can be time-consuming. Below, we then focus on PAC-Bayes algorithms working on a subset \mathcal{C} of $\mathcal{M}(\mathcal{H})$.

Instantiation and efficiency of PAC-Bayesian algorithms

A general pattern for PAC-Bayesian algorithms The introductory examples (1.7),(1.8) unveil a general design for any KL-based PAC-Bayesian algorithm, satisfying a trade-off between (i) the empirical risk, showing that the learner has to fit the training dataset, and (ii) a *regulariser* being a function of $\text{KL}(Q, P)$. This regulariser ensures that, during training, the learner will not overfit on training data. This training ensures a good generalisation ability as long as the associated generalisation bound is small.

While the conceptual ins and outs of PAC-Bayes algorithms are getting clearer, two unanswered questions remains:

1. How are those algorithms instantiated in practice?
2. Are these algorithms efficient and do they come with non-vacuous theoretical guarantees?

Instantiating a PAC-Bayes algorithm In practice, using a single prior P usually does not work, but it remains theoretically possible to consider a finite set of priors. Indeed, if one wants to consider k priors, then it is possible to consider k PAC-Bayes bounds holding for each of those priors with probability at least $1 - \frac{\delta}{k}$ and then consider a union bound, such a set of priors is called a *grid*. This method has been widely used in many PAC-Bayes work with clever grids, deteriorating initial bounds at the cost of supplementary $\log(n)$ or $\log \log(n)$ (divided by m), see *e.g.* ALQUIER (2024). This can also be used, for Catoni-typed algorithms, to the parameter λ . In both cases, considering grids allows to optimise on both the prior, the posterior (and possibly λ when involved) and then taking the closest value of those optimised parameters on the grid to still obtain theoretical guarantees. Another technique to ensure a good prior is to sacrifice a part of the training set to pre-train P . Doing so, the prior is then data-dependent and yields tighter bounds alongside increased performance (PEREZ-ORTIZ *et al.*, 2021a,c).

Efficiency of PAC-Bayes algorithms on supervised learning problems. The work of DZIUGAITE and ROY (2017) showed that optimising (1.7) when \mathcal{C} is a class of Gaussian measures for the weights of a deep neural network yields non-vacuous generalisation bound, meaning that the generalisation benefits of PAC-Bayesian training on deep nets can be theoretically ensured. Note that PAC-Bayesian bounds can also be used to quantify the generalisation ability of other learning algorithms, but the bound value is then suboptimal. DZIUGAITE and ROY (2017) used the toolbox described in the 'instantiation' paragraph, alongside a preliminary use of Stochastic Gradient Descent (SGD) to update Q before the PAC-Bayes training algorithm. This promising work paved the way to various extensions, providing non-vacuous guarantees for a wide range PAC-Bayes algorithms (LETARTE *et al.*, 2019; RIVASPLATA *et al.*, 2019; DZIUGAITE *et al.*, 2021; PEREZ-ORTIZ *et al.*, 2021a,b,c; BIGGS and GUEDJ, 2022a, 2023), showing that the PAC-Bayes toolbox provides elements of answer to understand the generalisation ability of neural networks. Beyond generalisation guarantees, PAC-Bayes bounds are also useful to propose original training methods, even if the associated guarantees are vacuous (BIGGS and GUEDJ, 2021, 2022b). Another important empirical use is to exploit PAC-Bayes bounds as correlation measures, to see whether a decrease of the bound is related to an increased generalisation ability of the learner. For instance NEYSHABUR *et al.* (2017) used McAllester's bound (1.3) as a 'flatness' measure and showed that it correlates well with a good generalisation ability for a few learning problems. This conclusion has been extended to a wider range of problems in DZIUGAITE *et al.* (2020) and JIANG *et al.* (2020).

PAC-Bayes algorithms beyond supervised learning. While supervised learning is a widely used to perform experiments in PAC-Bayes (often involving celebrated datasets such as MNIST or CIFAR-10), the McAllester bound holds for any learning problem with bounded loss, going beyond this setting. This theoretical flexibility has been exploited to derive PAC-Bayesian algorithm for various learning settings reinforcement learning (FARD and PINEAU, 2010), multi-armed bandits (SELDIN *et al.*, 2011, 2012b; SAKHI *et al.*, 2023), meta-learning (AMIT and MEIR, 2018; DING *et al.*, 2021; FARID and MAJUMDAR, 2021; ROTHFUSS *et al.*, 2021, 2022) to name but a few.

Is Example 1.1.1 tackled now? (DZIUGAITE and ROY, 2017) and following works have provided a positive answer by obtaining non-vacuous guarantees (sometimes tight) for $(\mathcal{H}_2, \mathcal{Z}, \ell)$ of Example 1.1.1 for various \mathcal{Z} (being, e.g., set of images for MNIST CIFAR-10 etc...). To obtain such guarantees, a PAC-Bayesian training needs to be performed to minimise its associated theoretical bound. That being said, several questions then legitimately emerge.

- Modern machine learning often implies learning problems where assumptions such as bounded (or subgaussian) losses or *i.i.d.* data do not hold. Is PAC-Bayes

theory extendable beyond those assumptions?

- As shown in DZIUGAITE and ROY (2017), the PAC-Bayesian training is often combined to another procedure (e.g. ERM) to yield non-vacuous bounds. However, PAC-Bayes bounds do not bring the theoretical understanding of such additional methods, often outputting deterministic predictors (*i.e.* Dirac distributions). This kind of predictor is not allowed in (1.3), (1.4). Is it possible to obtain PAC-Bayes bounds valid for such methods?

1.4 An optimisation perspective of PAC-Bayes

The questions raised at the end of the previous part are important as they underline a gap between the information-theoretic approach of PAC-Bayes bounds and practical optimisation. A supplementary example of this is the grid required in practice to optimise the prior (and/or λ in Catoni's bound). Indeed this hybrid solution is required to roughly fit theory, (exploiting a single prior) and practice (optimising freely the prior on a continuous space), while not being truly adapted to any of these settings. This then raises the following fundamental question:

Can we think PAC-Bayes learning from an optimisation perspective?

The elements of answer to this question are multiple. First, one can mix PAC-Bayes argument with geometric properties of optimisation procedure to obtain generalisation bounds designed for specific algorithms exploiting their geometric properties and assumptions, including but not limited to, SGD, Langevin dynamics (LONDON, 2017; DZIUGAITE and ROY, 2018a; NEU *et al.*, 2021; CLERICO *et al.*, 2022; HAGHIFAM *et al.*, 2023; ZHOU *et al.*, 2023). Those works shows both convergence properties as well as minimax rates, showing the impact of PAC-Bayes learning to provide a better theoretical understanding of the generalisation ability of concrete algorithms.

A second approach consists in describe general principles that should be satisfied by the various terms and assumptions in PAC-Bayes when looking at this through the prism of optimisation. We propose such an analysis below.

An optimisation-driven view of PAC-Bayes

- **Statistical assumptions.** While ℓ satisfies desirable geometric properties (convexity, gradient lipschitz ...), no statistical assumption is needed. However, the output of two runs of a stochastic optimisation algorithm on the same training set may vary a lot. For the specific case of SGD, many works shows that SGD exhibits a heavy-tailed behavior (see e.g. ŞİMŞEKLI *et al.*, 2019; ZHANG *et al.*, 2020; GÜRBÜZBALABAN *et al.*, 2021). Given that such heavy-tailed consideration emerges from the most celebrated algorithm, generalisation bounds, from

1.4. An optimisation perspective of PAC-Bayes

an optimisation point of view, should hold with weak statistical assumptions on the dataset, even if additional geometric assumptions on the loss may emerge.

- **The role of the prior.** The information-theoretic approach justify the Bayesian view of the prior as discussed earlier. In this spirit it is also possible to sacrifice a part of the training set (*i.e.* of the available information) to enrich P and then partially explain the efficiency of an information-theoretic training. Those two vision are not easily linked to optimisation concerns as the first one would be linked to a 'good' initialisation, something we cannot know in advance, while the second makes little sense as P is obtained through a first, unexplained, optimisation process which is necessary to understand the efficiency of the second part of training, outputting Q . From an optimisation stance, we suggest to assign only two possible roles to P : (i) the initialisation of the optimisation algorithm, then its impact should be attenuated through the learning process and (ii) a minimiser we aim to reach through optimisation. In this case, its impact is crucial as it translates the speed of convergence of our learning algorithms.
- **The place of stochastic predictors.** Involving a KL divergence as a complexity brings a particular focus on stochastic predictors, drawn from a distribution Q . Classical PAC-Bayes bounds usually focus on the average performance of such a predictor (hence the expectation over Q in (1.3),(1.4)), but recent extensions directly proposed guarantees for a single draw over Q (RIVASPLATA *et al.*, 2020; VIALARD *et al.*, 2023a). However, involving a KL implies that Q has to be absolutely continuous *w.r.t.* P , meaning that the support of Q cannot go beyond the one of P : this excludes the case of Dirac distributions, *i.e.* deterministic predictors. This is a clear limitation of the information-theoretic approach, as many learning algorithms outputs a deterministic predictor and thus, should be avoided to be in line with common practice in optimisation.

Those three points, while not necessarily considered explicitly through the lens of optimisation have been recently challenged.

PAC-Bayes beyond the usual setting

Recall that according to what we saw in McAllester's bound (1.3) and Catoni's one (1.4), we denote by usual setting a bound holding for *i.i.d.* \mathcal{S}_m , with bounded or subgaussian losses and involving a KL divergence as COMPLEXITY term. Many works overcame at least one of this assumption as precised below.

Beyond *i.i.d.* data The work of FARD and PINEAU (2010) established links between reinforcement learning and PAC-Bayes theory. This naturally led to the study of PAC-Bayesian bound for martingales instead of *i.i.d.* data (SELDIN *et al.*, 2011,

2012a,b). Also, PAC-Bayesian bound for lifelong learning (PENTINA and LAMPERT, 2014; FLYNN *et al.*, 2022) challenged also the *i.i.d.* assumption. We also denote that the PAC-Bayes bound for meta learning (AMIT and MEIR, 2018; DING *et al.*, 2021; FARID and MAJUMDAR, 2021; ROTHFUSS *et al.*, 2021, 2022) consider independent but non-identically distributed datasets (corresponding to different tasks).

Avoiding light-tailed losses. Light-tailed losses encompass bounded, subgaussian, subexponential losses. Deriving PAC-Bayes bound for heavy-tailed losses, starting from AUDIBERT and CATONI (2011) which provided PAC-Bayes bounds for least square estimators with heavy-tailed random variables. Their results was suboptimal with respect to the intrinsic dimension and was followed by further works from CATONI (2016) and CATONI and GIULINI (2017). More recently, this question has been addressed in the works of ALQUIER and GUEDJ (2018), HOLLAND (2019), KUZBORSKIJ and SZEPESVÁRI (2019), and HADDOUCHE *et al.* (2021), extending PAC-Bayes to heavy-tailed losses under additional technical assumptions.

Towards data-dependent priors. The work of (CATONI, 2007; LEVER *et al.*, 2010, 2013) proposed priors, not directly data-dependent, but depending of the data distribution \mathcal{D} when *i.i.d.* data are considered. can be informed by the data-generating distribution, PARRADO-HERNÁNDEZ *et al.* (2012), ONETO *et al.* (2016), DZIUGAITE and ROY (2017), and MHAMMEDI *et al.* (2019) also obtained PAC-Bayes bound with data-dependent priors by infusing directly data in the prior (and sacrificing a part of the dataset). The drawback of this method is that, in practice, such a prior allows tighter bounds, but at the cost of a reduced theoretical understanding as the prior is in practice often learned via ERM, and the PAC-Bayes bound hardly gives insights on what happens during this pre-training. Furthermore, if this pre-training has already made the bound converge to a minimum generalising well, then the PAC-Bayes training has no effect and the associated bound is no more than a test bound (the case $Q = P$). It has been shown for instance in (PEREZ-ORTIZ *et al.*, 2021a) that when P is trained with a consequent fraction of data, then the generalisation performance of the pre-trained P was roughly the same than Q , obtained from P after a PAC-Bayesian training. It is then unclear how impacting are PAC-Bayes methods compared to a test bound in this case. To alleviate this issue, another original route (DZIUGAITE and ROY, 2018b) exploits differential privacy to replace the data-free prior by a differentially private one, making possible to consider the prior as the learning objective (in their case a Gibbs posterior).

Beyond KL divergence. Several works allowed to extend PAC-Bayes beyond KL divergences. The most investigated route is to focus on the more general class of f -divergence, which include, e.g., KL, χ^2 , Rényi divergences among others (ALQUIER

1.4. An optimisation perspective of PAC-Bayes

and GUEDJ, 2018; OHNISHI and HONORIO, 2021; PICARD-WEIBEL and GUEDJ, 2022; VIALARD *et al.*, 2023a). However, f -divergences still implies absolute continuity of Q *w.r.t.* P . Another route recently emerged (AMIT *et al.*, 2022), replacing f -divergences by integral probability metrics (IPMs), finally allowing Dirac distribution in PAC-Bayes.

These works have sometimes been explicitly driven by optimisation considerations (DZ-IUGAITE and ROY, 2018b involved differential privacy to numerically tighten their bound without sacrificing data). However, in many cases, the information-theoretic vision of PAC-Bayes remained majoritary. In what follows, the contributions of this manuscript are designed *w.r.t.* the optimisation view of PAC-Bayes detailed above.

Contributions of this thesis

The contributions of this manuscript are motivated by optimisation considerations and are structured as follows:

- In Chapter 2, we propose novel PAC-Bayes bounds for martingale, with an application to multi-armed bandits. Those bounds are anytime-valid (*i.e.* for any dataset size simultaneously) and holds at the sole assumption of finite order 2 moments on both the posterior and the data distribution. Such weak statistical assumptions make these results applicable, for instance, for heavy-tailed SGD or many learning problems where optimisation procedure are performed regardless of the training set noise.
- Chapter 3 introduces *Online PAC-Bayes learning*, proposing theoretical bounds and learning algorithms involving a sequence of pairs (Q_i, P_i) , evolving through the optimisation process. Contrary to PAC-Bayes in a batch setting, the impact of $P = P_1$ is attenuated during the learning process, making Online PAC-Bayes useful when there is no prior information available, which is consistent with the vision of P as initialisation of a learning algorithm, while being only applicable, for now, to stochastic predictors as a KL divergence is involved.
- Chapter 4 still consider the prior as an initialisation point, but this time, considering batch learning algorithms. It is shown that the impact of the prior is attenuated by *flat minima*, *i.e.* minima such that their neighbourhood nearly minimises the loss. More generally, this chapter exhibits theoretical links between flat minima and generalisation and thus draw links between the benefits of a successful optimisation process (small gradients) and generalisation.
- Considering P as the learning objective allows to draw more explicit links between optimisation and generalisation. In Chapter 5, it is shown that the convergence

guarantees of *Bures-Wasserstein SGD*, a SGD-like algorithm on Gaussian measure spaces, can be directly incorporated within PAC-Bayes bounds, yielding interpretable results. This is possible by exploiting *Wasserstein PAC-Bayes learning*, which uses as `COMPLEXITY` term a 1-Wasserstein distance, allowing to trade statistical assumptions to geometric ones such as lipschitz or gradient-lipschitz losses.

- Wasserstein PAC-Bayes learning can also be exploited when P is seen as an initialisation point. In Chapter 6, we propose Wasserstein PAC-Bayes algorithms with associated theoretical bound for both batch and online learning. A notable strength of these methods is that they hold for deterministic predictors (Dirac distributions), making PAC-Bayes in line with a large part of optimisation algorithms.

To conclude this introduction we recap in Figures 1.1 and 1.2 the classical information-theoretic vision of PAC-Bayes alongside the original optimisation view proposed above.

PAC-BAYESIAN BOUNDS FOR MARTINGALES AND HEAVY-TAILED LOSSES

This chapter is based on the following paper

MAXIME HADDOUCHE and BENJAMIN GUEDJ. PAC-Bayes Generalisation Bounds for Heavy-Tailed Losses through Supermartingales. *Transactions on Machine Learning Research*. (2023)

Abstract

TODO: put general bounds for martingales and batch learning as corollary

MITIGATING INITIALISATION IMPACT BY REAL-TIME CONTROL: ONLINE PAC-BAYES LEARNING

This chapter is based on the following papers

MAXIME HADDOUCHE and BENJAMIN GUEDJ. Online PAC-Bayes Learning. *Advances in Neural Information Processing Systems (NeurIPS)*. (2022)

MAXIME HADDOUCHE and BENJAMIN GUEDJ. PAC-Bayes Generalisation Bounds for Heavy-Tailed Losses through Supermartingales. *Transactions on Machine Learning Research*. (2023)

PAUL VIALARD, MAXIME HADDOUCHE, UMUT SIMSEKLI, and BENJAMIN GUEDJ. Learning via Wasserstein-Based High Probability Generalisation Bounds. *Advances in Neural Information Processing Systems (NeurIPS)*. (2023b)

Contents

4.1	Introduction	42
-----	------------------------	----

Abstract

Put OPB here. Precise in the intro that the martingale bounds allow to go beyond batch learning but that this has never been made for OL. Put the supermartingale OPB bound in a supplementary section and the Online WPB bound after the main results of OPB to reach heavy-tailed losses.

MITIGATING INITIALISATION IMPACT THROUGH FLAT MINIMA: FAST RATES FOR SMALL GRADIENTS

This chapter is based on the following paper

TODO

Contents

5.1	Introduction	44
-----	------------------------	----

Abstract

This is the PLS paper, precise that the supermartingales bounds are richer than simply recovering classical batch guarantees: we can incorporate gradient norms, which explains generalisation when a flat minima is reached.

4.1 Introduction

WASSERSTEIN PAC-BAYES LEARNING: EXPLOITING OPTIMISATION GUARANTEES TO EXPLAIN GENERALISATION

This chapter is based on the following papers

MAXIME HADDOUCHE and BENJAMIN GUEDJ. Wasserstein PAC-Bayes Learning: A Bridge Between Generalisation and Optimisation. *arXiv*. abs/2304.07048. (2023)
PAUL VIALARD, MAXIME HADDOUCHE, Umut SIMSEKLI, and BENJAMIN GUEDJ. Learning via Wasserstein-Based High Probability Generalisation Bounds. *Advances in Neural Information Processing Systems (NeurIPS)*. (2023b)

Contents

6.1	Introduction	46
-----	------------------------	----

Abstract

Put WPB here, precise that, when the prior is seen as the learning goal, it is possible for a certain optimisation algorithm to directly incorporate sound geometric optimisation guarantee into a generalisation bound, trading the hope to reach a flat minima with a sound convergence guarantees. However, this comes at the cost of the explicit impact of the dimension. Also put the paper with Paul(batch bounds) as a supplementary content.

5.1 Introduction

WASSERSTEIN PAC-BAYES IN PRACTICE: LEARNING ALGORITHMS WITH GUARANTEES FOR DETERMINISTIC PREDICTORS

This chapter is based on the following paper

TODO

Contents

A.1	JENSEN's Inequality	47
A.2	MARKOV's Inequality	47
A.3	Ville's Inequality	48

Abstract

This is the Wasserstein paper with Paul: practical transition to PAC-Bayes with both batch and online approach. Pb: the batch approach use data-dependent priors: does not fit the story as it is an information theoretic wiw and should be precised.

6.1 Introduction

SOME MATHEMATICAL TOOLS

A.1 Jensen's Inequality

Theorem A.1.1 (JENSEN's Inequality). Let X a random variable following a probability distribution ν with f a real-valued measurable convex function, we have

$$f\left(\mathbb{E}_{X \sim \nu}[X]\right) \leq \mathbb{E}_{X \sim \nu}[f(X)].$$

Proof. Since $f()$ is a convex function, the following inequality holds, i.e., we have

$$\forall X', \quad a\left(X' - \mathbb{E}_{X \sim \nu}[X]\right) \leq f(X') - f\left(\mathbb{E}_{X \sim \nu}[X]\right),$$

where a is the tangent's slope. By taking the expectation to both sides of the inequality, we have

$$\underbrace{a\left(\mathbb{E}_{X \sim \nu}[X] - \mathbb{E}_{X \sim \nu}[X]\right)}_{=0} \leq \mathbb{E}_{X \sim \nu}[f(X)] - f\left(\mathbb{E}_{X \sim \nu}[X]\right).$$

Hence, by rearranging the terms, we prove the claimed result. ■

A.2 Markov's Inequality

Theorem A.2.1 (MARKOV's Inequality). Let X a non-negative random variable following a probability distribution ν and $\delta > 0$, we have

$$\mathbb{P}_{X \sim \nu}[X \geq \delta] \leq \frac{\mathbb{E}_{X \sim \nu}[X]}{\delta}.$$

Proof. First of all, remark that we have the following inequality for any X

$$\delta \mathbb{1}[X \geq \delta] \leq X \mathbb{1}[X \geq \delta] \leq X. \quad (\text{A.1})$$

Indeed, on the one hand, if $X < \delta$, $\mathbb{1}[X \geq \delta] = 0$, the inequality holds trivially. On the other hand, if $X \geq \delta$, $\mathbb{1}[X \geq \delta] = 1$ and the inequality becomes $\delta \leq X$, which is true. By taking the expectation of Equation (A.1), we have

$$\mathbb{E}_{X \sim \nu} [\delta \mathbb{1}[X \geq \delta]] \leq \mathbb{E}_{X \sim \nu} [X].$$

From the fact that the expectation of a constant is the constant and by definition of the probability, we have

$$\delta \mathbb{P}_{X \sim \nu} [X \geq \delta] \leq \mathbb{E}_{X \sim \nu} [X] \iff \mathbb{P}_{X \sim \nu} [X \geq \delta] \leq \frac{\mathbb{E}_{X \sim \nu} [X]}{\delta},$$

which is the desired result. ■

A.3 Ville's Inequality

Lemma A.3.1 (Ville's maximal inequality for supermartingales). Let (\mathcal{F}_t) be a filtration and (Z_t) a non-negative super-martingale satisfying $Z_0 = 1$ a.s. If Z_t is adapted to \mathcal{F}_t and $\mathbb{E}[Z_t | \mathcal{F}_{t-1}] \leq Z_{t-1}$ a.s., $t \geq 1$, then, for any $0 < \delta < 1$, it holds

$$\mathbb{P}(\exists T \geq 1 : Z_T > \delta^{-1}) \leq \delta.$$

Proof. We apply the optional stopping theorem (DURRETT, 2019, Thm 4.8.4) with Markov's inequality defining the stopping time $i = \inf\{t \geq 1 : Z_t > \delta^{-1}\}$ so that

$$\mathbb{P}(\exists t \geq 1 : Z_t > \delta^{-1}) = \mathbb{P}(Z_i > \delta^{-1}) \leq \mathbb{E}[Z_i] \delta \leq \mathbb{E}[Z_0] \delta \leq \delta. \quad \blacksquare$$

Abstract. In machine learning, a model is learned from data to solve a task automatically. In the supervised classification setting, the model aims to predict the label associated with an input. The model is learned using a limited number of examples, each consisting of an input and its associated label. However, the model's performance on the examples, computed by the empirical risk, does not necessarily reflect the performance on the task, which is represented by the true risk. Moreover, since it is not computable, the true risk is upper-bounded by a generalization bound that mainly depends on two quantities: the empirical risk and a complexity measure. One way to learn a model is to minimize a bound by a type of algorithm called self-bounding. PAC-Bayesian bounds are well suited to the derivation of this type of algorithm. In this context, the first contribution consists in developing self-bounding algorithms that minimize PAC-Bayesian bounds to learn majority votes. If these bounds are well adapted to majority votes, their use for other models becomes less natural. To overcome this difficulty, a second contribution focuses on the disintegrated PAC-Bayesian bounds that are natural for more general models. In this framework, we provide the first empirical study of these bounds. In a third contribution, we derive bounds that allow us to incorporate complexity measures defined by the user.

Keywords. Machine Learning, Generalization, PAC-Bayesian Bound, Disintegrated PAC-Bayesian Bound, Self-Bounding Algorithm, Majority Vote, Neural Network, Complexity Measure.

Résumé. En apprentissage automatique, un modèle est appris à partir de données pour résoudre une tâche de manière automatique. Dans le cadre de la classification supervisée, le modèle vise à prédire la classe associée à une entrée. Le modèle est appris à l'aide d'un nombre limité d'exemples, chacun étant constitué d'une entrée et de sa classe associée. Cependant, la performance du modèle sur les exemples, calculée par le risque empirique, ne reflète pas nécessairement la performance sur la tâche qui est représentée par le risque réel. De plus, n'étant pas calculable, le risque réel est majoré pour obtenir une borne en généralisation qui dépend principalement de deux quantités : le risque empirique et une mesure de complexité. Une façon d'apprendre un modèle est de minimiser une borne par un type d'algorithme appelé auto-certié (ou auto-limitatif). Les bornes PAC-Bayésiennes sont bien adaptées à la dérivation de ce type d'algorithmes. Dans ce contexte, la première contribution consiste à développer des algorithmes auto-certiés qui minimisent des bornes PAC-Bayésiennes pour apprendre des votes de majorité. Si ces bornes sont bien adaptées aux votes de majorité, leur utilisation pour d'autres modèles devient moins naturelle. Pour pallier cette difficulté, une seconde contribution se concentre sur les bornes PAC-Bayésiennes désintégrées qui sont naturelles pour des modèles plus généraux. Dans ce cadre, nous apportons la première étude empirique de ces bornes. Dans une troisième contribution, nous dérivons des bornes permettant d'incorporer des mesures de complexité pouvant être définies par l'utilisateur.

Mot-clés. Apprentissage Automatique, Généralisation, Borne PAC-Bayésienne, Borne PAC-Bayésienne Désintégrée, Algorithme Auto-certié, Algorithme Auto-limitatif, Vote de Majorité, Réseau de Neurones, Mesure de Complexité.
